The "Witty" Worm

- Released March 19, 2004.
- Exploited flaw in the passive analysis of Internet Security Systems products
- Worm fit in a single Internet packet
 - Stateless: When scanning, worm could "fire and forget"
- Vulnerable pop. (12K) attained in 75 minutes.
- Payload: slowly corrupt random disk blocks.
- Flaw had been announced the *previous day*.
- · Written by a Pro.

What Exactly Does Witty Do?

- 1. Seed the PRNG using system uptime.
- 2. Send 20,000 copies of self to randomly selected destinations.
- 3. Open physical disk chosen randomly between 0 .. 7.
- 4. If success:
- 5. Overwrite a randomly chosen block on this disk.
- 6. Goto line 1.
- 7. Else:
- 8. Goto line 2.

Witty Telescope Data

- UCSD telescope recorded every Witty packet seen on /8 (2²⁴ addresses).
 - But with unknown losses
- In the best case, we see ≈ 4 of every 1,000 packets sent by each Witty infectee.
- ? What can we figure out about the worm?

Generating (Pseudo-)Random Numbers

 Linear Congruential Generator (LCG) proposed by Lehmer, 1948:

$$X_{i+1} = X_i^*A + B \mod M$$

• Picking A, B takes care, e.g.:

```
A = 214,013

B = 2,531,011

M = 2^{32}
```

- Theorem: the *orbit* generated by these is a complete permutation of 0 .. 2^{32} -1
- Another theorem: we can invert this generator

```
srand(seed) \{ X \leftarrow seed \}
rand() { X ← X*214013 + 2531011; return X }
main()

 srand(get_tick_count());

2. for(i=0;i<20,000;i++)
       dest\_ip \leftarrow rand()_{[0..15]} || rand()_{[0..15]}
3.
       dest\_port \leftarrow rand()_{[0..15]}
4.
       packetsize \leftarrow 768 + rand()_{[0..81]}
5.
6.
       packetcontents \leftarrow top-of-stack
7.
       sendto()
8. if(open\_physical\_disk(rand()_{[13..15]}))
       write(rand()<sub>[0..14]</sub> || 0x4e20)
9.
10.
       goto 1
11. else goto 2
```

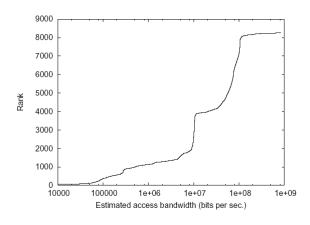

What Can We Do Seeing Just 4 Packets Per Thousand?

- Each packet contains bits from 4 consecutive PRNGs:
 - 3. $dest_{ip} \leftarrow rand()_{[0..15]} || rand()_{[0..15]}$
 - 4. $dest_port \leftarrow rand()_{[0..15]}$
 - 5. $packetsize \leftarrow 768 + rand()_{[0..8]}$
- If first call to rand() returns X_i:
 - 3. $dest_{ip} \leftarrow (X_i)_{[0..15]} || (X_{i+1})_{[0..15]}$
 - 4. $dest_port \leftarrow (X_{l+2})_{[0..15]}$
- Given top 16 bits of X_i, now brute force all possible lower 16 bits to find which yield consistent top 16 bits for X_{i+1} & X_{i+2}
- ⇒ Single Witty packet suffices to extract infectee's complete PRNG state! Think of this as a sequence number.

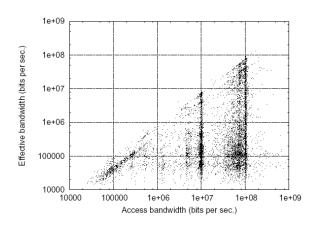

Cool, But So What?

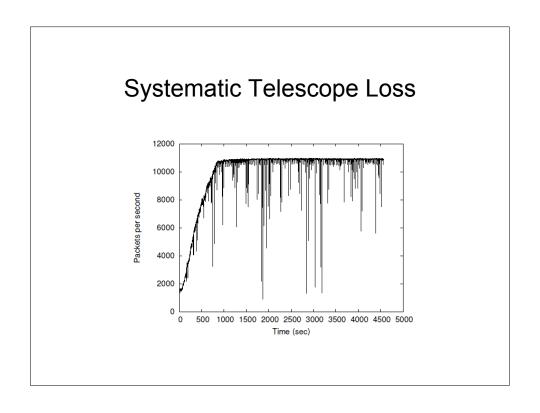

- E.g., Individual Access Bandwidth Estimation
 - Suppose two consecutively-observed packets from source S arrive with states X_i and X_i
 - Compute j-i by counting # of cranks forward from X_i to reach X_i
 - # packets sent between the two observed = (j-i)/4
 - sendto call in Windows is blocking
 - Ergo, access bandwidth of that infectee should be
 (j-i)/4 * size-of-those-packets / ΔT
 - Note: works even in the presence of <u>very heavy</u> packet loss

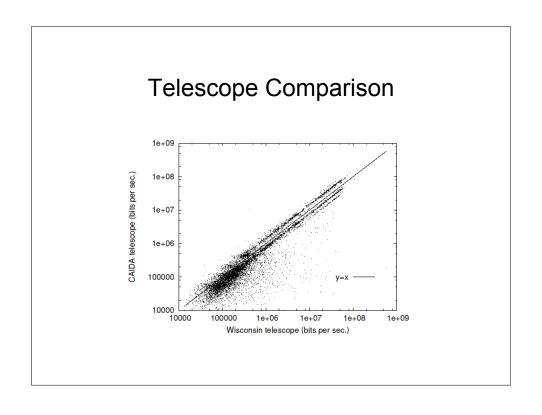

Precise Bandwidth Estimation vs. Rates Measured by Telescope

Telescope Bias

srand(seed) \{ X \leftarrow seed \}
rand() { X ← X*214013 + 2531011; return X }
main()
1.
     srand(get_tick_count());
     for(i=0;i<20,000;i++)
        dest\_ip \leftarrow rand()_{[0..15]} \mid\mid rand()_{[0..15]}
3.
        dest\_port \leftarrow rand()_{[0..15]}
                                                            4 calls to rand()
4.
                                                            per loop
        packetsize \leftarrow 768 + rand()<sub>[0..8]</sub>
5.
6.
        packetcontents ← top-of-stack
7.
        sendto()
                                                        Plus one more every 20,000
     if(open_physical_disk(rand()<sub>[13..15]</sub> ))
8.
                                                       packets, if disk open fails ...
9.
        write(rand()_{[0..14]} || 0x4e20)
10.
         goto 1
                           } ... Or complete reseeding if not
11. else goto 2
```

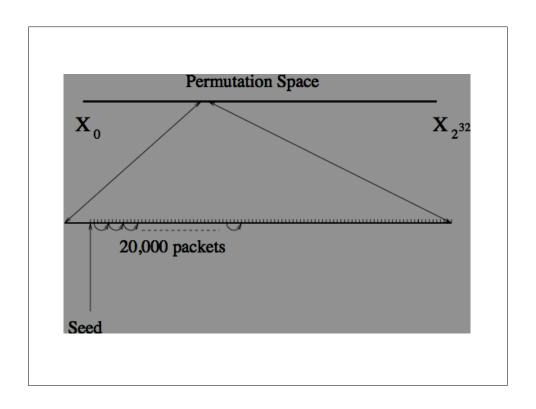

Witty Infectee Reseeding Events

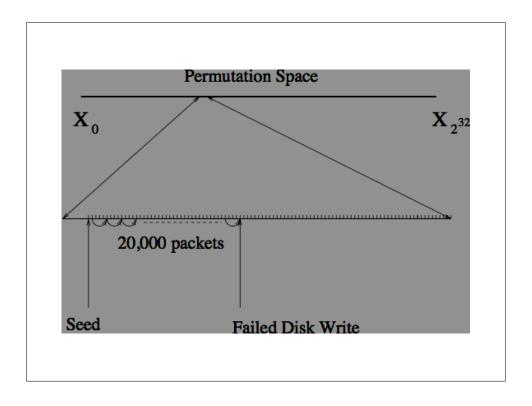

- For packets with state X_i and X_i:
 - If from the same batch of 20,000 then
 - $j i = 0 \mod 4$
 - If from separate but adjacent batches, for which Witty <u>did not</u> reseed, then
 - $j i = 1 \mod 4$

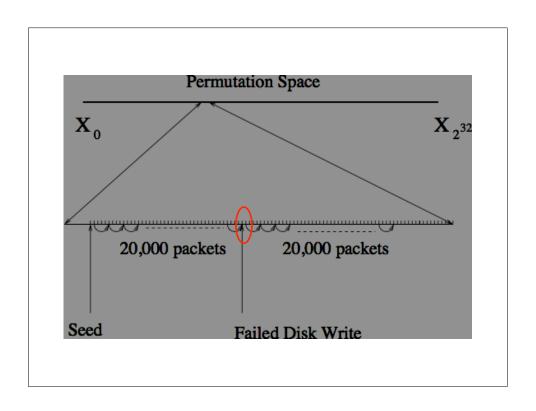

(but which of the 100s/1000s of intervening packets marked the phase shift?)

 If from batches across which Witty reseeded, then no apparent relationship.

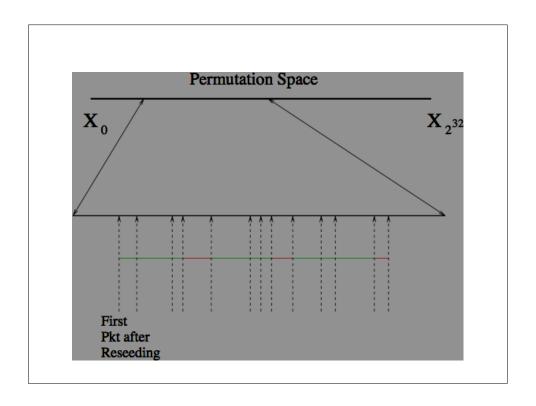

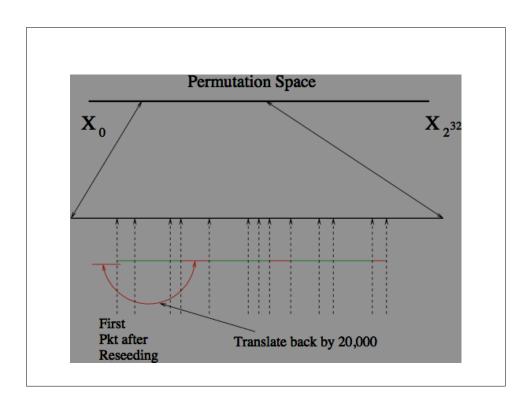

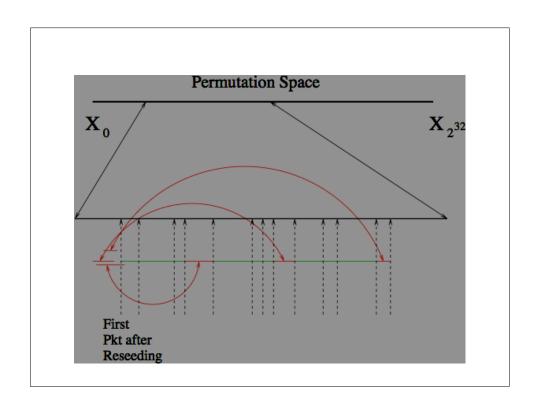

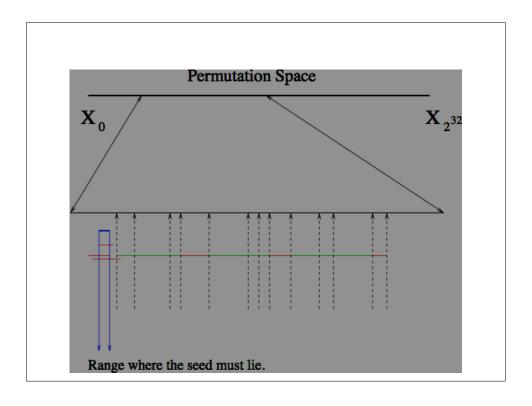

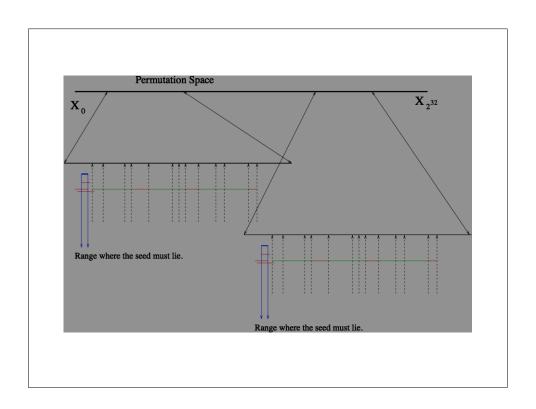

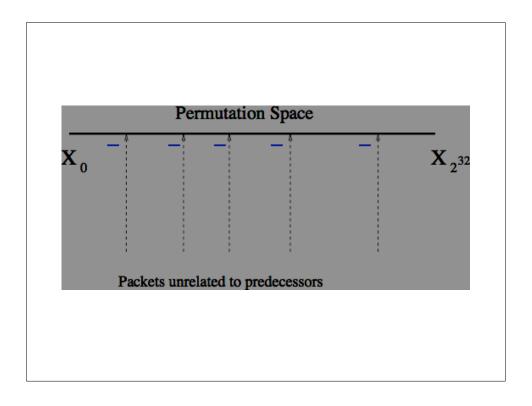

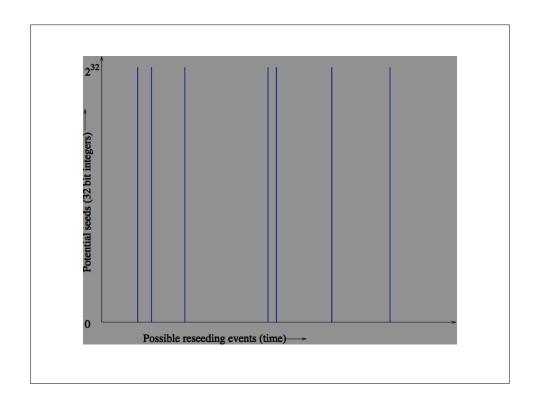

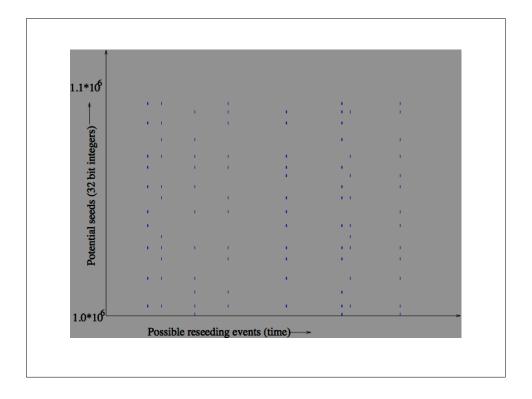

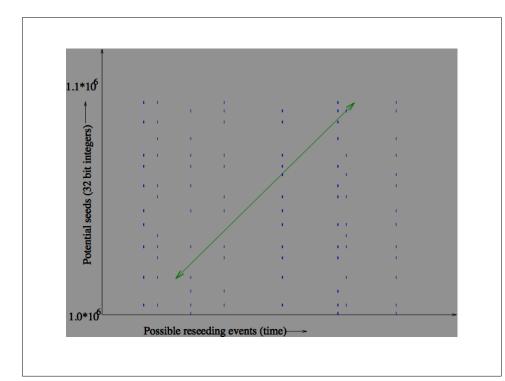

We Know Intervals in Which Each First-Seed Packet Occurs

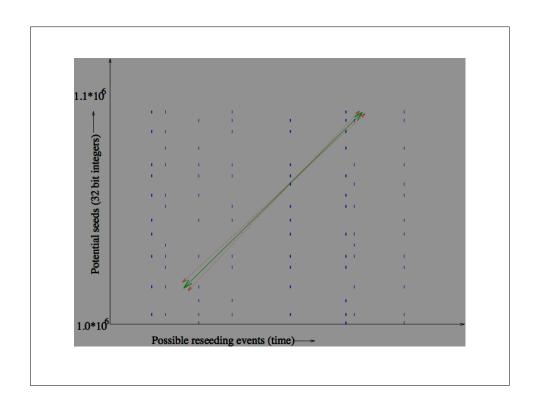

- ... but which among the 1,000s of candidates are the actual seeds?
- Entropy isn't all that easy to come by ...
- Consider

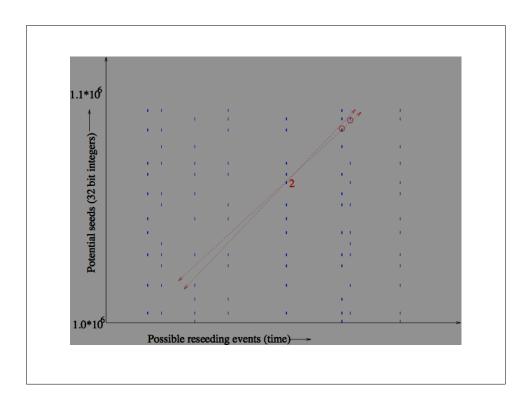

srand(get_tick_count())

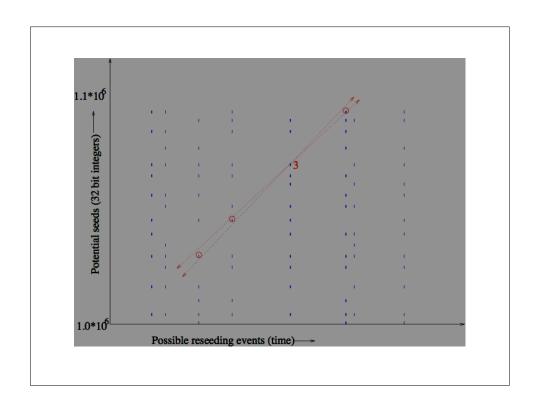

i.e., uptime in msec

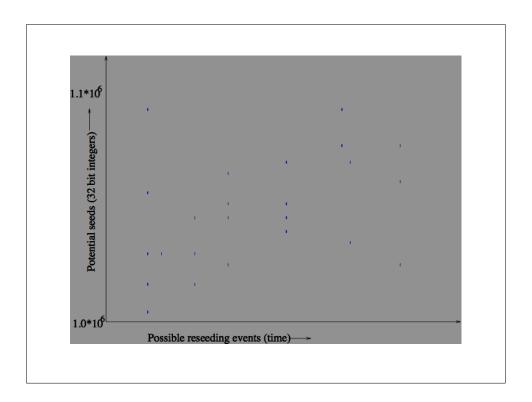

• The values used in repeated calls increase <u>linearly with time</u>

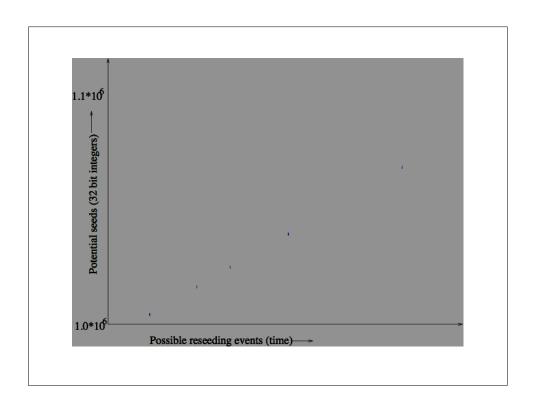

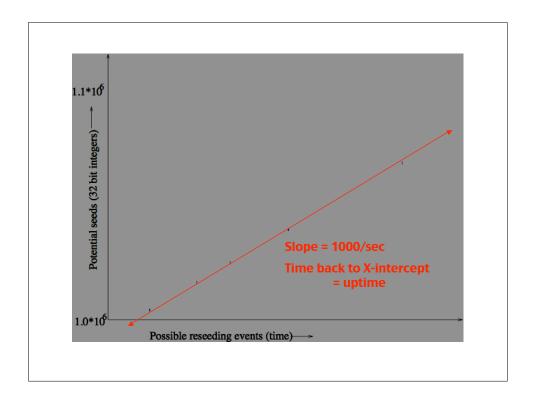

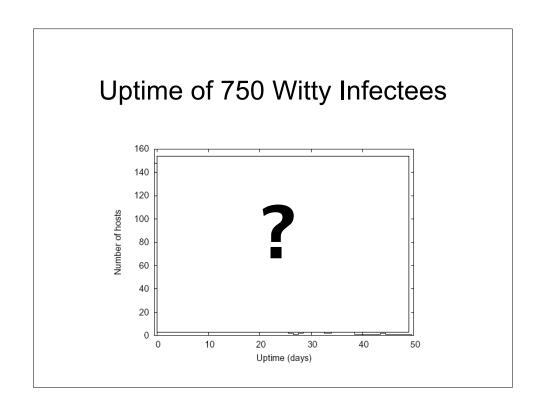

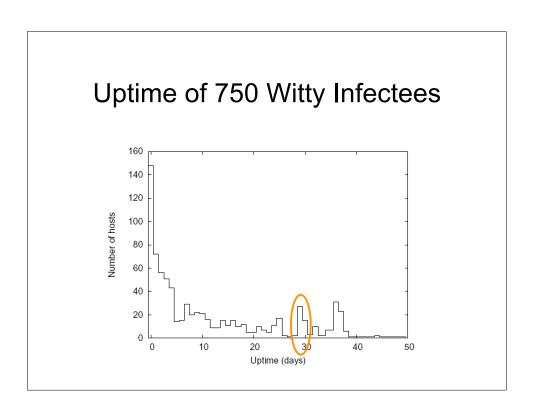

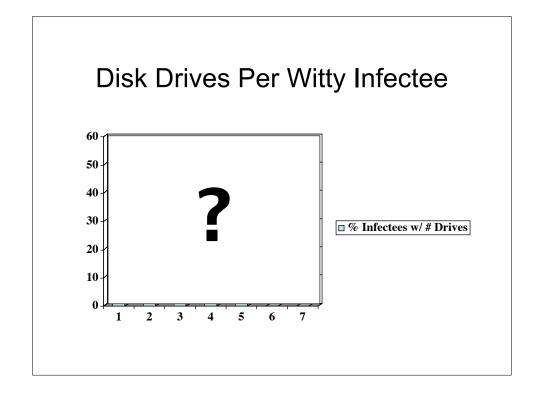

Given Exact Values of Seeds Used for Reseeding ...

 ... we know exact random # used at each subsequent disk-wipe test:

 $if(open_physical_disk(\textbf{rand}()_{[13..15]}\,)\\$

• ... and its success, or failure, i.e., <u>number of drives attached</u> to each infectee ...

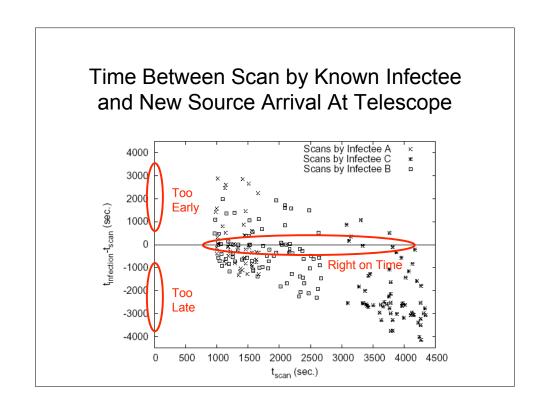

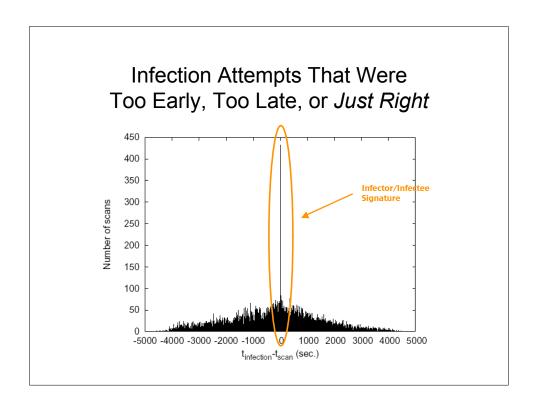

Given Exact Values of Seeds Used for Reseeding ...

 ... we know exact random # used at each subsequent disk-wipe test:

if(open_physical_disk(rand()[13,15])

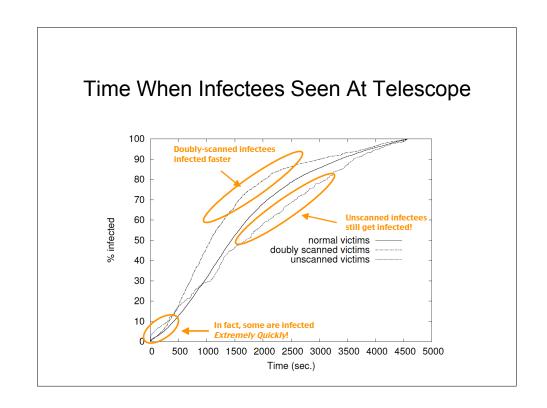

- ... and its success, or failure, i.e., <u>number of</u> drives attached to each infectee ...
- ... and, more, generally, every packet each infectee sent
 - Can compare this to when new infectees show up
 - i.e. Who-Infected-Whom

Witty is Incomplete

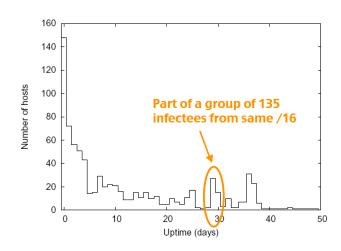

- Recall that LCD PRNG generates a complete orbit over a permutation of 0..2³²-1.
- But: Witty author didn't use all 32 bits of single PRNG value
 - $dest_{ip} \leftarrow (X_i)_{[0..15]} || (X_{i+1})_{[0..15]}$
 - Knuth recommends top bits as having better pseudo-random properties
- But²: This does not generate a complete orbit!
 - Misses 10% of the address space
 - Visits 10% of the addresses (exactly) twice
- · So, were 10% of the potential infectees protected?

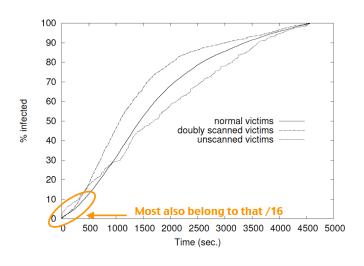

How Can an Unscanned Infectee Become Infected?

- · Multihomed host infected via another address
 - Might show up with normal speed, but not early
- · DHCP or NAT aliasing
 - Would show up late, certainly not early
- Could they have been passively infected extra quickly because they had <u>large cross-</u> sections?
- Just what are those hosts, anyway?

Uptime of 750 Witty Infectees

Analysis of the Extra-Quick Hosts

- Initial infectees exhibit super-exponential growth ⇒ they weren't found by random scanning
- Hosts in prevalent /16 numbered x.y.z.4 in consecutive /24 subnets
- "Lineage" analysis reveals that these subnets not sufficiently visited at onset to account for infection
- One possibility: they monitored networks separate from their own subnet
- But: if so, strange to number each .4 in adjacent subnets ...
- ⇒ Unlikely infection was due to passive monitoring ...

Alternative: Witty Started With A "Hit List"

- ...Unlikely infection was due to passive monitoring ...
- Prevalent /16 = <u>U.S. military base</u>
- Attacker knew of ISS security software installation at military site ⇒ ISS insider (or ex-insider)
- Fits with very rapid development of worm after public vulnerability disclosure

Are All The Worms In Fact Executing Witty?

- · Answer: No.
- There is *one* "infectee" that probes addresses **not on the orbit.**
- Each probe contains Witty contagion, but lacks randomized payload size.
- Shows up very near beginning of trace.
- ⇒ Patient Zero machine attacker used to launch Witty. (Really, Patient Negative One.)
 - · European retail ISP.
 - Information passed along to Law Enforcement.

Summary of Witty Telescope Forensics

- Understanding a measurement's <u>underlying</u> <u>structure</u> adds enormous analytic power
- Cuts both ways: makes anonymization much harder than one would think
- With enough effort, worm "attribution" can be possible
 - But a *lot* of work
 - And no guarantee of success
